The first model for the distribution of ions near the surface of a metal electrode was devised by Helmholtz in 1874. He envisaged two parallel sheets of charges of opposite sign located one on the metal surface and the other on the solution side, a few nanometers away, exactly as in the case of a parallel plate capacitor.

After a brief presentation of the major aspects involving supercapacitors, their fundamental aspects were reviewed with special emphasis on recent advances accounting for the electric double layer models proposed for porous carbon-based electrodes containing electrochemically active sub-nanometer pores.

Electrochemical capacitors (ECs), variously referred to by manufacturers in promotional literature as "supercapacitors" or "ultracapacitors," store electrical charge in an electric double layer at the interface between a high-surface-area carbon electrode and a liquid electrolyte.^{1,2}Consequently, they are also quite properly referred to as electric double layer capacitors.

Carbon-carbon supercapacitors use the cheapest technology due to the low price of activated carbon. These systems function on the basis of the Gouy-Chapmann and Stern-Geary electrochemical double-layer theory.¹¹ The charge is stored through the adsorption of the electrolyte ions on large-surface-area activated carbon (2300 m²/g). There is no charge-transfer reaction occurring during the charge-discharge process.
